Abstract

Purpose Phosphodiesterase type-5 inhibitor administration in diabetic men with erectile dysfunction (ED) is associated with reduced waist circumference. We evaluated potential effects of daily tadalafil administration on body composition and investigated its possible mechanism(s) of action in C₂C₁₂ skeletal muscle cells in vitro.

Methods Forty-three men on stable caloric intake (mean age 48.5 ± 7; BMI 25.5 ± 0.9 kg/m²) complaining mild ED and/or low urinary tract symptoms (LUTS) were randomly assigned to receive tadalafil (TAD) 5 mg/daily (once-a-day=OAD-TAD; n = 23) or 20 mg on-demand (on-demand=OD-TAD; n = 20) for 2 months. Primary outcomes were variations of body composition measured by Dual-energy X-ray absorptiometry; secondary outcomes were ED/LUTS questionnaire scores along with hormone (testosterone, estradiol, insulin) and endothelial function (Endopat2000) variations.

Results OAD-TAD increased abdominal lean mass (*p* < 0.01) that returned to baseline after 2 months withdrawal.

LUTS scores improved (*p* < 0.01) in OD-TAD while ED scores improved (*p* < 0.01) in both groups. We found significant improvements in endothelial function (*p* < 0.05) that directly correlated with serum insulin (*p* < 0.01; *r* = 0.3641) and inversely correlated with estradiol levels (*p* < 0.01; *r* = 0.3655) even when corrected for potential confounders. Exposure of C₂C₁₂ cells upon increasing tadalafil concentrations (10⁻⁷ to 10⁻⁶ M) increased total androgen receptor mRNA and protein expression as well as myogenin protein expression after 24 and 72 h (2.8 ± 0.4-fold and 1.4 ± 0.02-fold vs. control, respectively, *p* < 0.05).

Conclusions Daily tadalafil improved lean mass content in non-obese men probably via enhanced insulin secretion, estradiol reduction, and improvement of endothelial function in vivo. The in vitro increased myogenin and androgen receptor protein expression in skeletal muscle cells suggests a translational action of phosphodiesterase type-5 on this receptor.

Introduction

Phosphodiesterases (PDEs) are a family of enzymes with different selectivity for cyclic nucleotides, cAMP, and cGMP, [1] that play several regulatory roles such as platelet aggregation, T-cell activation, and smooth cell relaxation and vascular tone [2, 3]. In addition, the NO-cGMP signaling pathway seems to play an important role in the regulation of muscle metabolism [4] and insulin action [5].

PDE₅ inhibitors (PDE₅i) are selective blockers of the cGMP-hydrolyzing enzyme. In men with erectile dysfunction (ED) chronic PDE₅i improves insulin secretion, [6] endothelial function, [7] and in vitro it regulates aromatase (ARO) expression both in adipocyte [8] and osteoblast cell models. [9] Interestingly, data from experimental rabbit model of high fat diet-induced metabolic syndrome (MetS) confirms that tadalafil (TAD) administration not only after long-term (12 weeks), but even after a short-term exposure (1 week), in vivo and in vitro, was able to restore a correct pre-adipocyte commitment, through a positive effect on insulin sensitivity, and to upregulate, via PKG activation, the genes related to mitochondrial biogenesis and brown adipogenesis, including UCP₁ [10]. Studies in men with type-2 diabetes (T₂D) confirmed that chronic sildenafil administration was able to reduce epicardial adipose tissue and in a murine diabetic model regulated visceral adiposity by shifting adipose tissue cell composition toward a less inflamed profile [11]. No data on possible effects of PDE₅ inhibitors on lean mass in humans have been described yet.

We aimed to investigate the potential effects of daily TAD treatment on lean mass, hormonal, and endothelial function in men with mild ED and/or LUTS. We additionally used C₂C₁₂ skeletal muscle cell line to evaluate the in vitro effect of TAD during myogenic differentiation by the analysis of skeletal muscle-specific differentiation-dependent markers.

Materials and methods

Study design

This was an open label, parallel arm design study aimed to determine the potential effects of TAD assumption on body composition. Forty three male subjects (≥ 18 years–BMI $\geq 18.5 \leq 25$ kg/mg²) affected by mild ED and/or LUTS were enrolled. They were randomly allocated to receive either TAD 5 mg/daily (OAD-TAD; $n = 23$) or TAD 20 mg on-demand (OD-TAD; $n = 20$) for 2 months. Three scheduled visits were planned: baseline, 2-months after each respective treatment, and 2 months follow-up, with following evaluations: general physical examination, anthropometric parameters [body weight (BW), height, BMI, and waist circumference (WC)]; body composition [fat mass (FM), lean mass (FFM)], endothelial function, fasting serum sample, International Index of Erectile Function-5 items (IIEF-5), and International Prostate Symptom Score (IPSS) questionnaires.

Primary outcomes were variations from baseline of body composition; secondary outcomes were variations from baseline of the IIEF-5, IPSS, total testosterone (TT), 17 β -estradiol (E), T/E ratios, fasting insulin levels, endothelial function (TBo). The clinical study was carried out in an in-

office setting at Sapienza University of Rome and each patient signed a detailed informed consent (Study ID 2369, committee approval #166/12); ClinicalTrials.gov (NCT02554045). To clarify the potential cellular and molecular mechanisms on body composition, in vitro experiments were performed to further highlight intracellular events triggered by TAD exposure in skeletal muscle cells. Thus, C₂C₁₂ cell line was used to investigate the effects of TAD on myogenic differentiation. Given that testosterone (T)-androgen receptor (AR) signaling pathway plays an important role in early myogenesis [12, 13] by increasing AR expression during C₂C₁₂ differentiation [14] and that TAD increases AR expression and T release in human osteoblasts, we evaluated effects on AR expression during early stages of muscle cells differentiation.

Exclusion criteria

IIEF5 < 17 (patients with severe ED), IPSS > 7 (patients with severe LUTS), any concomitant treatment during the prior 3 months, lifestyle, diet or physical exercise changes attended within the 16 weeks of study duration; patients potentially trying to become father; significant hepatic, respiratory, hematological or renal disease; history of drugs or alcohol abuse; history or presence of any cancer; any other reason that the investigator feels precludes patients safety.

Dual-energy X-ray absorptiometry (DEXA) assessment

Body composition was evaluated by DEXA (DEXA-Hologic QDR-1000), according to previously published procedures [15]. We modified calculations for android abdominal section, by using the area included between the line joining the last inferior ribs and the line joining the superior iliac spines. Long-term precision error was 0.54% (phantom); short-term precision error was 1.2% for the lumbar spine and 2% for the femoral neck. Fat Free Mass (FFM) and Fat Mass (FM) was expressed in grams per square centimeter (g). DEXA soft tissue measurements variation coefficient was FFM: 1.067% and FM: 1.748%.

Endothelial function

Endothelial function was investigated by peripheral arterial tonometry (PAT; EndoPAT2000, Itamar Medical), according to previously published procedures [16]. Instead of the natural logarithm of PAT ratio, we evaluated the average amplitude of PAT signal in the post-occlusion period (test signal, T) compared with that in the baseline (B) signal before occlusion, utilizing the same time intervals as for reactive hyperemia index (RHI) calculation, but not indexed to controlateral arm (referred to as T/Bo ratio), as previously published [17].

Laboratory analyses

TT and E were measured by chemiluminescence micro-particle immunoassay (CMIA, Architect System, Abbott Laboratories, IL, USA), with a detection limit of 0.28 nmol/L and 10 pg/mL, respectively (intra-assay and interassay coefficients of variation for TT: 2.1 and 3.6% at 10.08 nmol/L), with reference values 2.8–11 ng/mL (T) and 25–107 pg/mL (E₂). Insulin levels were analyzed by immunometric assay based on chemiluminescence using an automated clinical chemistry analyzer (Immulite 2000, Diagnostic Product Corp., Los Angeles, CA, USA) [18].

Cell culture and treatments

C₂C₁₂ skeletal muscle cells (CRL-1772; American Type Culture Collection, Manassas, VA, USA) were cultured in Dulbecco's modified Eagle medium without phenol red (DMEM; Euroclone, Milan, Italy) supplemented with 10% heat-inactivated fetal bovine serum (Invitrogen, Carlsbad, CA, USA) and 1% penicillin and streptomycin (Sigma-Aldrich, St. Louis, MO, USA) under an atmosphere of 5% CO₂ in humidified air at 37 °C. In all experiments, cells were seeded at the density of 10⁴ cells/cm² and allowed to grow until 80% confluence. To induce myogenic differentiation, fetal bovine serum content was lowered to 2%. TAD (kindly supplied by ELI Lilly ICOS Corporation) was added after the induction of myogenic differentiation. Cells were harvested for molecular analysis after 12, 24, 48, and 72 h of differentiation.

Protein extraction and immunoblot analysis

Following treatments, cells were washed with PBS and lysed in fresh ice-cold RIPA buffer (Sigma-Aldrich) supplemented before use with protease and phosphatase inhibitor cocktails (Roche, Indianapolis, IN, USA). Lysates were precleared by centrifugation and protein content was measured using Pierce[®] BCA protein assay kit (Thermo Fisher Scientific, Waltham, MA, USA). Samples were boiled for 5 min; then an equal amount of protein extracts (15–30 µg) was resolved in SDS-polyacrylamide gels (10–14%) and transferred to polyvinylidene difluoride (PVDF) membranes (Amersham Biosciences, Piscataway, NJ, USA). Membranes were saturated by incubation at room temperature for 1 h with 5% (w/v) non-fat dry milk in 20 mM Tris–HCl, 150 mM NaCl, 0.1% Tween 20, and incubated with specific first antibodies (1:1000) overnight at 4 °C. Antibodies against class I myosin (MyoD), Myogenin, and myosin heavy chain (MyHC) (H300) were from Santa Cruz Biotechnology (Dallas, Texas, USA); AR, CYP19, and β-actin antibodies from Cell Signaling Technology (Danvers, MA, USA); β-actin and GAPDH antibodies from

Sigma-Aldrich. Immunoreactive protein bands were detected by incubation for 1 h with horseradish peroxidase-conjugated secondary goat anti-rabbit (1:10000, Merck Millipore, Billerica, MA, USA) or goat anti-mouse (1:10000, Sigma-Aldrich) in blocking solution at room temperature, visualized by enhanced chemiluminescence (Amersham Biosciences), then bands were obtained on the ImageQuant LAS 4000 (GEHC).

Immunofluorescence and myogenic differentiation assays

Cells were washed twice with cold PBS, fixed with 4% formaldehyde, permeabilized with 0.2% Triton X-100 in PBS and fixed in blocking solution (6 ng/ml IgG from goat serum in PBS) for 30 min. Cells were incubated with anti-MyHC antibody (1:300, Santa Cruz Biotechnology) overnight at 4 °C. Alexa Fluor 488-conjugated anti-rabbit IgG (H + L) was used as secondary antibody (1:500, Thermo Fisher Scientific). After counterstaining with 4',6-Diamidino-2-phenylindole dihydrochloride (DAPI; 500 ng/ml), slides were mounted with Prolong Gold Antifade Reagent (Invitrogen).

Myogenic differentiation was evaluated by calculating differentiation and fusion indexes representing the proportion of nuclei that were localized within MyHC-positive myotubes and the formation of multinucleated myotubes, respectively. Fluorescent images of random fields were captured with 20× magnification. For each experimental condition, total number of nuclei and number of nuclei incorporated into the myotubes were counted. The differentiation index was calculated as the percentage of MHC-positive cells above total and fusion index was determined by the percentage of nuclei incorporated into myotubes (defined as containing at least two nuclei) relative to the total number of nuclei.

Measurement of mRNA levels by quantitative RT-PCR

RNA was extracted using the TRI reagent (Sigma) and subjected to DNase digestion (Thermo Fisher Scientific). Real-time quantitative PCR was conducted using One-step SYBR GreenER (Thermo Fisher Scientific) in a 7500 Real-time PCR System (Applied Biosystems). Specific primers were as follows: Fw *Ar* (5'-TACCAGCTCACCAAGCTCCT-3'); Rv *AR* (5'-GATGGGCTTGA CTTTCCCAG-3'); Fw *Cyp19* (5'-AACCCATGCAGTA-TAATGTCAC-3'); Rv *Cyp19* (5'-AGGACCTGGTATT-GAAGACGAG-3'); Fw *Cyclophilin A* (5'-GTCAACCC ACCGTGTTCTT-3'); Rv *Cyclophilin A* (5'-CTGCTGT CTTGGGACCTTGT-3'). Each analysis was performed in triplicate sessions. Relative expression levels were calculated using the comparative cycle threshold (ΔΔCt) method using *Cyclophilin A* as internal control.

ELISA assay

After 24 and 72 h of differentiation in the presence or absence of TAD, media were removed and centrifuged at 500g for 10 min at 4 °C, and supernatants stored at –80 °C until used for assays. *T* was measured by sensitive ELISA kit (Enzo Life Sciences, Inc., Plymouth Meeting, PA, USA) assay. Data from ELISA assay in the supernatants were normalized for number of viable cells at the end of each experiment and expressed in pg/ml. The sensitivity of T kit is 2.6 pg/ml with a range of detection between 3.9 and 1000 pg/ml.

Statistical analysis

For the clinical study, results are reported as mean \pm standard error when normally distributed, and as median (quartiles) when non-parametric. Data were analyzed using *t*-tests for single comparisons, analysis of covariance for comparisons at specific time points, using baseline score as a covariate. Multiple stepwise regression analysis was performed to determine associations between serum endothelial function, E and insulin concentration after adjusting for potential confounders such as age, cigarette smoking, and drug/supplemental facts assumption. A *p*-value < 0.05 was considered statistically significant. Statistical analysis was performed using the computer statistical package SPSS 11.0 (SPSS Inc., Chicago, IL, USA).

For the in vitro study, all results represent the means \pm SD of at least three independent experiments, and *p*-values were calculated using the unpaired *t*-test.

Results

TAD improves body composition in vivo

After 2 months of both TAD treatments, no significant changes in total BW or overall FFM/FM were found (Table 1). Interestingly, 2 months OAD-TAD induced an increase in FFM (expressed as percentages) both at the trunk (Fig. 1a; *p* < 0.01) and android sections (Fig. 1b; *p* < 0.001) that was lost after 2 months withdrawal, whereas a similar trend in appendicular FFM was also found (data not shown). Accordingly, OAD-TAD produced a trend to reduction in WC (–2.5 cm, Table 1), with significant reduction of abdominal FM (%) only at the android section that returned to baseline after 2 months from withdrawal (Fig. 1c; *p* < 0.01). IIEF-5 questionnaire also showed a significant improvement for both treatment groups (Table 1; *p* < 0.01), while IPSS scores improved significantly in OAD-TAD only (*p* < 0.01). OAD-TAD induced a significant drop in E levels (*p* < 0.001) while no modifications in circulating TT levels were found, determining significant reduction of T/E ratio (Table 1; *p* < 0.01) that returned to baseline after withdrawal.

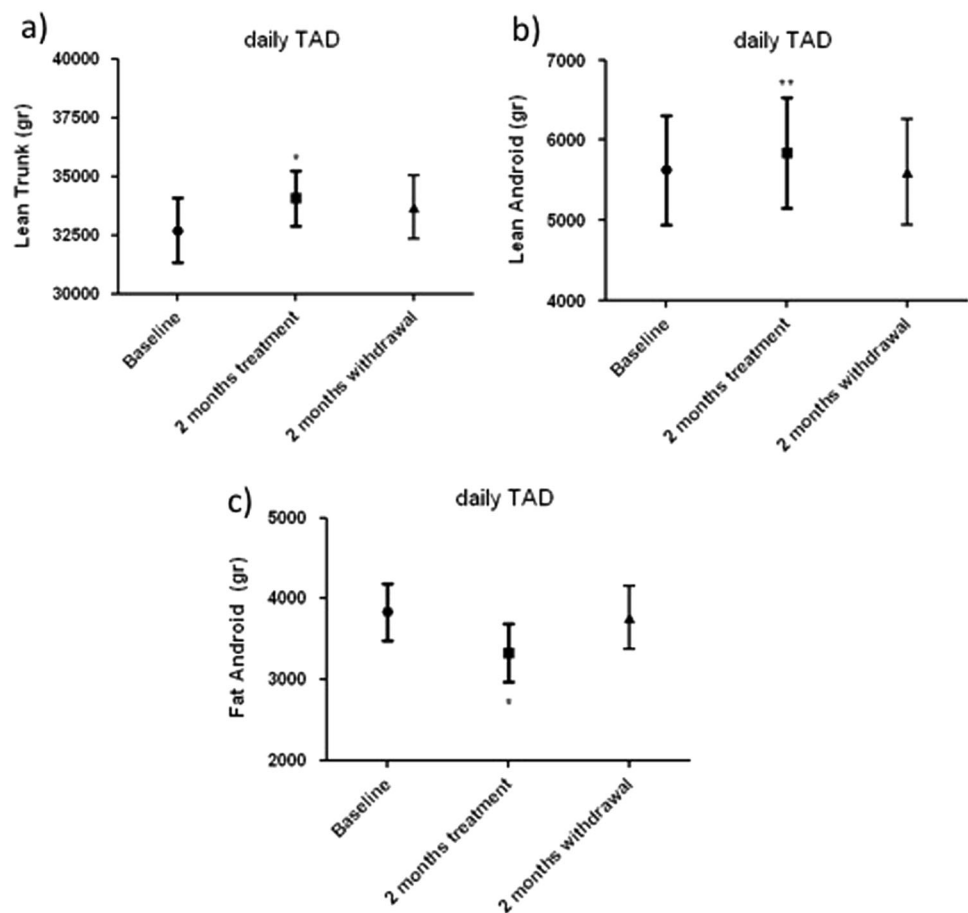

Endothelial function (T/Bo) showed significant improvement after 2 months OAD-TAD (Fig. 2a; *p* < 0.01) that returned at baseline after withdrawal. Improvements in endothelial function showed a direct correlation with insulin (Fig. 2b; *p* < 0.01, *r*: 0.3641) and an inverse correlation with E serum levels (Fig. 2c; *p* < 0.01, *r*: 0.3655), respectively. No differences in body composition, endothelial function,

Fig. 1 Differences after daily TAD treatment in lean and FM (gr=grams) from baseline. Daily TAD 5 mg produced **a)** significant variation in lean trunk fat ($p < 0.01$, 2-months vs. baseline) that returned at baseline levels after 2 months from withdrawal; **b)** significant variation android trunk lean mass (gr) ($p < 0.001$ —2-months vs. baseline) that returned at baseline levels after 2 months from withdrawal. Also, **c)** a significant variation in android trunk FM (gr) ($p < 0.01$ —2-months vs. baseline) that returned at baseline value after 2 months from withdrawal was found

and T/E ratios were found after OD-TAD treatment. Side effects were those commonly reported with TAD administration (headache and myalgia) did not differ between the two groups and did not determine drug discontinuation (data not shown).

TAD modulates myogenic differentiation in C₂C₁₂ skeletal muscle cells in vitro

For in vitro experiments, TAD concentrations were chosen (10^{-7} to 10^{-6} M) based on previous studies [8, 9, 19], indicating these concentrations as likely equivalent to the doses used for in vivo treatment. To evaluate potential effect of TAD on initiation of differentiation program, cells were treated with increasing concentrations of TAD and key myogenic differentiation markers, such as MyoD, myogenin, and MyHC, were analyzed after 24 and 72 h exposure by western blot analysis.

TAD (10^{-7} to 10^{-6} M) induced a 3.3 ± 0.7 -fold and a 3.9 ± 0.9 -fold increase in MyoD protein expression after 24 h exposure as compared with untreated cells, while TAD (10^{-6} M) induced a myogenin protein expression increase of

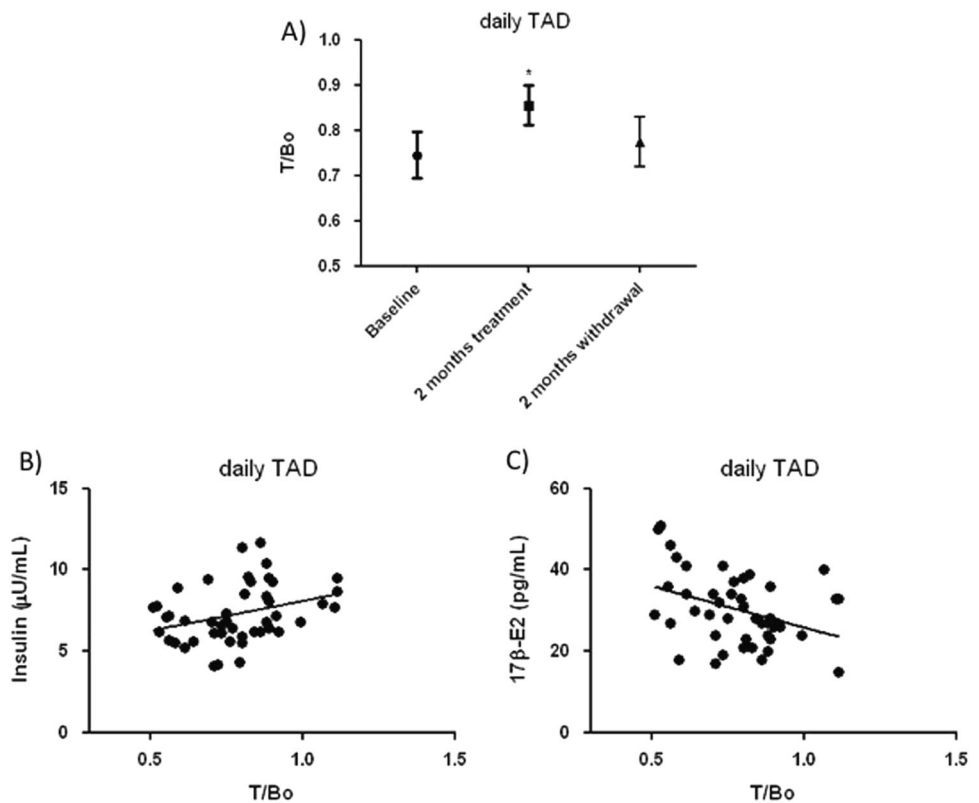

2.8 ± 0.4 -fold and 1.4 ± 0.02 -fold vs. control cells after 24 and 72 h, respectively. The same concentrations of TAD (10^{-7} to 10^{-6} M) induced 1.4 ± 0.07 -fold and 1.6 ± 0.2 -fold increase in MyHC protein expression, respectively, after 24 h (Fig. 3a, b).

Fusion index for myotubes formation in the differentiated cells increased after 72 h of about 30% from the onset of differentiation process upon 10^{-6} M TAD exposure as compared with untreated cells (Fig. 3d, e). Preliminary experiments, performed to demonstrate lack of cytotoxicity effects and to assess cell viability, by trypan blue exclusion assay and MTS assay, did not demonstrate differences between treated and untreated cells (data not shown).

TAD increases AR expression

As depicted in Fig. 4a, RT-qPCR analysis revealed a 1.3 ± 0.08 -fold increase of AR mRNA content in cells treated with 10^{-6} M TAD for 12 h ($p < 0.05$) reaching a 1.5 ± 0.08 -fold increase after 24 h ($p < 0.05$) as compared with untreated cells. Increase was lost after 48 h. Western blot analysis further supported an increase in AR protein

Fig. 2 Treatment with daily TAD treatment produced a significant improvement of **a**) endothelial function (T/Bo, $p < 0.05$; 2-months vs. baseline) that returned at baseline levels after 2 months from withdrawal. Endothelial function (T/Bo) directly correlated with **b**) insulin ($p < 0.01$; $r = 0.3641$) and inversely correlated with **c**) E serum levels ($p < 0.01$; $r = 0.3655$), respectively

expression (2.0 ± 0.3 -fold) in TAD-treated vs. untreated cells ($p < 0.05$) (Fig. 4b). Since a rapid regulation of *Cyp19* (ARO) mRNA and protein level was previously observed in TAD-treated human adipocytes, eight potential modulations were evaluated in muscle cells as well. TAD (10^{-6} M) induced a 1.4 ± 0.07 -fold increase of *Cyp19* mRNA expression in the cells 12 h after the differentiation induction ($p < 0.05$, data not shown), but the effect was blunted after 24 h. Moreover, western blot analysis showed a 2.5 ± 0.7 -fold increase of *Cyp19* protein levels in TAD-treated cells at 24 h and a return to control level after 48 h ($p < 0.05$, data not shown).

In accordance with an upregulation of AR expression, a relevant increase of T concentrations in the supernatant of 10^{-6} M TAD-treated cells (2.3 ± 0.5 -fold compared with untreated cells, $p < 0.05$) was found after 24-h treatment, that was also blunted after 48 h (data not shown). Unfortunately, it was not possible to detect E levels in C_2C_{12} supernatant cells, since values resulted too low as with commercial high sensitive ELISA kits available (data not shown).

Since T regulates PDE₅ expression and responsiveness to TAD in human corpus cavernosum, [20] the expression level of this enzyme was evaluated during C_2C_{12} muscle cells differentiation with or without TAD. PDE_{5a} mRNA

level increased after 48-h differentiation into myotubes (1.5 ± 0.02 vs. undifferentiated cells, data not shown), confirming previous studies in human primary skeletal muscle cells [21]. By contrast, TAD did not affect PDE_{5a} mRNA expression in the same experimental conditions.

Discussion

This is the first demonstration that shows that short-term daily TAD administration improves body composition in men by concomitant increases in FFM and decreases in FM with a tendency to decrease in WC. These latter results are in line with studies in vivo in the rabbit model, showing beneficial effects of TAD on visceral adipose tissue pre-adipocyte phenotype and amelioration of MetS features, that were corroborated by further demonstrating an in vitro upregulation of expression of genes related to brown/beige commitment, and mitochondrial fusion. [10] In our young healthy subject affected by mild ED/LUTS, we found interesting modifications in hormonal milieu, i.e., higher T/E ratio and increased insulin production, along with multivariate analysis showing significant association with insulin, E plasma levels, and endothelial function. This

Fig. 3 TAD effect on muscle cells differentiation and myotube formation in vitro. C₂C₁₂ muscle cells were induced to differentiate in the presence or absence of different concentrations of TAD (10⁻⁷ to 10⁻⁶ M). Cell lysates were collected after 24 and 72 h of differentiation and analyzed by Western blotting. **a**) Representative Western blot analysis of MyoD, Myogenin and MyHC protein contents **b**) Histograms represent mean values of MyoD, Myogenin and MyHC protein

levels ratio normalized over the GAPDH protein level **c**) Representative image of immunofluorescence staining for MyHC after 72 h of differentiation. Differentiation **d**) and fusion indexes **e**) in cells treated with or without TAD (10⁻⁷ to 10⁻⁶ M) were calculated as reported in materials and methods. Results are presented as mean ± SD (n = 3) from three different experiments. Scale bars = 75 μm; ** p ≤ 0.01 and * p ≤ 0.05 vs. untreated cells

result was relevant, since obtained with no changes either in lifestyle and/or physical activity during the study.

The efficacy of long-term treatment with PDE₅i awaits demonstration in human metabolic diseases, i.e., T₂D and MetS. Preclinical data suggest that cGMP signaling affects energy balance, insulin resistance, and glucose metabolism, and might be related to vasodilation (resulting in increased perfusion and substrate delivery to metabolically active skeletal muscle)—through direct effects on peripheral glucose handling [22, 23]. Chronic treatment with sildenafil in a mouse model of diet-induced insulin resistance caused a significant improvement in energy expenditure and insulin sensitivity [24]. In animal models, chronic sildenafil improved cardiac performance [25] and reduced interstitial cardiac fibrosis [26]. In men with T₂D, Fiore et al. demonstrated that daily sildenafil improved WC and

epicardial fat, and demonstrated that this occurred by regulation of miR22 release and SIRT1.[11] Also Ramirez et al. demonstrated that chronic sildenafil administration in overweight men with pre-diabetes enhanced insulin sensitivity and improved markers of endothelial function [27]. Hill et al. demonstrated that TAD administration (10 mg on alternate days for 3 weeks in men with MetS) was associated with improved pancreatic β-cell function, as assessed by oral glucose tolerance testing, when compared with placebo [28]. Accordingly, acute TAD administration had beneficial effects on peripheral microcirculation and glucose uptake also in insulin-resistant diabetic women [29]. Recent discoveries support the evidence that endothelial dysfunction may be the cause of insulin resistance and T₂D, due to a decrease in NO levels, reducing cGMP production, and impairing muscle glucose uptake [30]. Due to TAD action

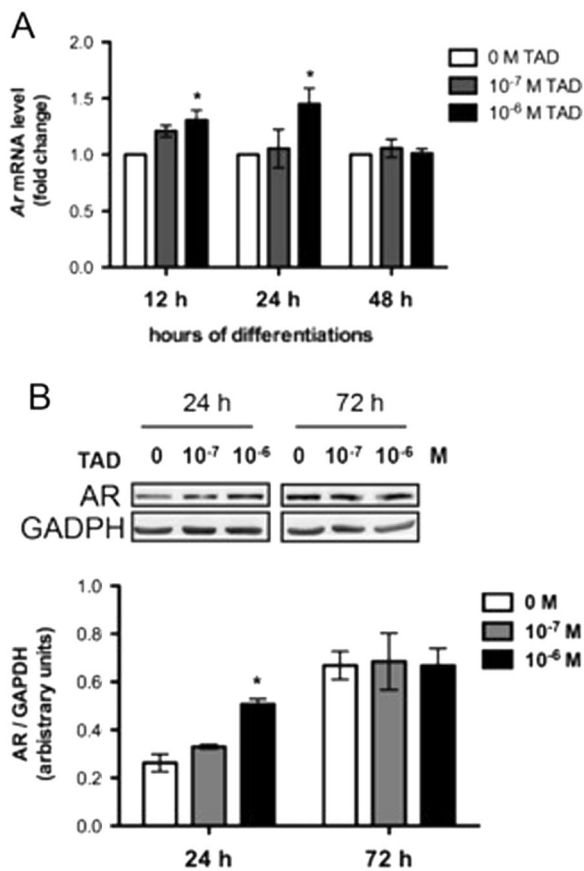

Fig. 4 Effects of TAD (10^{-7} to 10^{-6} M) on **a**) AR mRNA expression levels after 12, 24, and 48 h the onset of differentiation; **b**) AR protein expression after 24 and 72 h of differentiation. * $p \leq 0.05$ vs. untreated cells

on insulin and on glucose metabolism in C_2C_{12} cells, [12] we further investigated possible acceleration of myogenic differentiation and an increased AR expression in these cells. The underlying mechanisms by which T/AR signalling regulates metabolic homeostasis in men are complex, but evidences derived from various AR knockout mouse models reveal tissue-specific AR signalling that are involved in the regulation of metabolism [31]. MyoD and Myogenin regulate the program of skeletal muscle differentiation: in fact, MyoD plays a crucial role in cells commitment to myogenesis program, while myogenin takes part in the execution of differentiation program [32]. Indeed, we found a relevant increase of MyoD accumulation after 24 h of differentiation. It is known that the muscle-regulatory transcription factor myogenin appears at a later stage leading to the commitment of differentiation; [33] interestingly, TAD-treated cells showed an earlier transcription after 24 h differentiation when compared with the control ones. MyHC is part of sarcomeric structure of skeletal muscle and occurs at the end terminal differentiation into functional myotube [34]. When the cells were treated with TAD, it was observed an increase of MyHC expression and myotube fusion index

after 72 h from the onset of differentiation. Since clinical study showed a clear increase in T/E ratio, [35] a more favorable androgen milieu is hypothesized in vivo that could activate AR transduction cascade involved in myogenesis. This pathway may determine a more selective modulation of AR and acceleration of the differentiation process in skeletal muscle cells in vitro, [36] suggesting that this event might be one of the potential mechanism leading to the improvement of FFM in our clinical study. The possible relationship between TAD use, AR pathway physiology, muscle cell differentiation, and hormones adaptation [37] should be evaluated in healthy athletes abusing with TAD [38] and androgenic anabolic steroids.

We recognize several limitations of this study. Despite any changes in lifestyle or caloric intake were permitted to patients throughout the entire study duration, the lack of a placebo arm limits the interpretation of our results. It is important to recognize that DEXA may not accurately assess body composition when compared with CT-scans, but mostly in markedly obese subjects. No evaluation of inflammation markers was provided. In addition, although in vitro results suggest a possible role of AR signalling pathway in mediating TAD effects on skeletal muscle cell differentiation, further studies are warranted to elucidate the translational mechanisms involved in TAD effects on skeletal muscle myogenesis.

In conclusion, we demonstrated for the first time that TAD exerts modulatory effects on body composition in vivo in metabolically healthy men and on skeletal muscle cell differentiation in vitro. As expected, mild ED symptoms improved in both groups, while LUTS amelioration was evident during daily administration only. The hormonal and microcirculation variations induced by TAD in clinical subjects accompanied by in vitro muscle cell line differentiation suggest a translational action of PDE ϵ i on skeletal muscle possibly mediated via AR.

Funding This study was funded by MIUR Grants (grant number 2015XCR88M_008 to Prof. Antonio Aversa and 052013 to Prof. Silvia Migliaccio) and Ministry of Health Grant (grant number 00829 to Prof. Andrea Lenzi).

Compliance with ethical standards

Competing interests The authors declare that they have no competing interest.

Ethical approval All procedures performed in studies involving human participants were in accordance with the ethical standards of the institutional and/or national research committee and with the 1964 Helsinki declaration and its later amendments or comparable ethical standards (NCT Identifier: NCT02554045).

Informed consent Informed consent was obtained from all individual participants included in the study.

Animal Rights This article does not contain any studies with animals performed by any of the authors.
